Abstract

Background: Previous studies of conduct disorder (CD) have reported structural and functional alterations in the limbic system. However, the white matter tracts that connect limbic regions have not been comprehensively studied. The uncinate fasciculus (UF), a tract connecting limbic to prefrontal regions, has been implicated in CD. However, CD-related alterations in other limbic tracts, such as the cingulum and the fornix, have not been investigated. Furthermore, few studies have examined the influence of sex and none have been adequately powered to test whether the relationship between CD and structural connectivity differs by sex. We examined whether adolescent males and females with CD exhibit differences in structural connectivity compared to typically-developing controls.

Methods: We acquired diffusion-weighted MRI data from 101 adolescents with CD (52 females) and 99 controls (50 females). Data were processed for deterministic spherical deconvolution tractography. Virtual dissections of the UF, the three subdivisions of the cingulum (retrosplenial, parahippocampal and subgenual cingulum), and the fornix were performed and measures of fractional anisotropy (FA) and hindrance-modulated orientational anisotropy (HMOA) were analysed.

Results: The CD group had lower FA and HMOA in the right retrosplenial cingulum tract relative to controls. Importantly, these effects were moderated by sex - males with CD significantly lower FA compared to male controls, whereas CD and control females did not differ.

Conclusions: Our results highlight the importance of considering sex when studying the neurobiological basis of CD. Sex differences in retrosplenial cingulum connectivity may contribute to sex differences in the clinical presentation of CD.

Word count abstract: 248

1 **Introduction**

2 Conduct Disorder (CD) is diagnosed in children and adolescents who display a pattern of behaviour in
3 which societal rules and the rights of others are violated (American Psychiatric Association, 2013).
4 Although the lifetime prevalence of CD is higher amongst males than females (by a ratio of
5 approximately 2.4:1), it is increasingly prevalent in adolescent females. Individuals with CD have poor
6 prognoses with negative adult outcomes that include criminality, alcohol abuse, unemployment, and
7 poor mental and physical health. CD is one of the main reasons for referral to child and adolescent
8 mental health services, and places a high burden on the affected individuals, families and society in
9 general. Therefore, CD can be considered a major mental and public health priority and gaining a better
10 understanding of its neurodevelopmental underpinnings is critical.

11

12 It has been proposed that limbic system dysfunction may underlie antisocial behaviour. Brain regions
13 that make up the limbic system include the anterior cingulate cortex (ACC) and posterior cingulate
14 cortex (PCC), orbitofrontal cortex (OFC), ventromedial prefrontal cortex (vmPFC), hippocampus,
15 hypothalamus, amygdala, and medial temporal lobe (Rolls, 2004, 2013). The limbic system is involved
16 in emotion processing and regulation, reward-related decision-making and a range of other cognitive
17 functions (Blair, 2008). Evidence implicating limbic brain structures in antisocial behaviour comes
18 from a number of sources. Two structural magnetic resonance imaging (sMRI) meta-analyses
19 concluded that the most robust abnormalities in grey matter volumes observed in this population are in
20 limbic brain structures, such as the amygdala, ACC and vmPFC (Aoki et al., 2014; Raschle et al., 2015;
21 Rogers and De Brito, 2016). In line with this, a recent meta-analysis of fMRI studies reported that CD
22 individuals consistently displayed underactivation in the ACC and vmPFC during tasks involving
23 emotion processing, and 'hot' (motivationally-relevant) executive functions, and in dorsolateral
24 prefrontal cortex (dlPFC), dorsal ACC, and hippocampus during 'cool' (non-affective) executive
25 function tasks (Alegria et al., 2016).

26

27 Given this evidence for structural alterations and abnormal neural activity in limbic regions in
28 individuals with CD, it is possible that the structural connections linking these regions are also
29 compromised. The major limbic system white matter (WM) pathways include the fornix, the cingulum,
30 and the uncinate fasciculus (UF; Catani et al., 2013). Structural connectivity and the micro-structural
31 properties of brain tissue are frequently assessed using diffusion tensor imaging (DTI) techniques
32 (Catani and Thiebaut de Schotten, 2012). However, previous DTI studies in youths with CD and related
33 disorders have had several limitations. First, the majority of DTI studies in CD have focused on males
34 (although see Menks et al., 2017). Therefore, possible sex differences in the microstructural integrity
35 of limbic system-related tracts have not been investigated. This is important as the neurobiological basis
36 of CD has been shown to differ in several respects between males and females (Fairchild et al., 2013;

3

37 Decety et al., 2015; Smaragdi et al., 2017). Only one small study directly compared males and females
38 with CD (n=14 and 13, respectively) in terms of WM microstructure (Zhang et al., 2014). It
39 investigated fractional anisotropy (FA) values of the UF using deterministic tractography (which
40 investigates specific anatomical pathways). Interestingly, the authors found higher FA values in the UF
41 in males, but not females, with CD. These preliminary findings suggest that WM microstructural
42 alterations in temporo-frontal regions might be specific to males with CD.
43
44 Additionally, aside from one very recent study (Sethi et al., 2018), previous studies using DTI-based
45 tractography methods in individuals with CD have largely focused on the UF tract (Passamonti et al.,
46 2012; Sarkar et al., 2013; Zhang, Gao, et al., 2014). The fact that these studies focused on this tract may
47 have been due to earlier studies in adults with antisocial personality disorder (ASPD; an adult condition
48 of which CD is an antecedent) and psychopathy, finding lower FA in the UF in these individuals
49 compared to healthy controls (Craig et al., 2009). However, opposite findings have been reported in
50 youths with CD, who show higher FA values in the UF relative to healthy controls (Passamonti et al.,
51 2012; Sarkar et al., 2013; Zhang, Gao, et al., 2014). Similarly, a study investigating the dorsal and
52 ventral components of the cingulum tract, reported lower radial diffusivity (RD) in the dorsal cingulum
53 bundle in individuals with CD compared to controls (Sethi et al., 2018). This was opposite to the pattern
54 observed in adults with ASPD (Sethi et al., 2014). Several authors have suggested that the opposite
55 patterns observed in WM microstructural measures in youths and adults might be due to abnormally
56 accelerated maturation of WM tracts in individuals with CD (Passamonti et al., 2012; Sarkar et al.,
57 2013b; Zhang, Gao, et al., 2014). Although these previous studies were important first steps in
58 understanding CD-related alterations in structural connectivity, the focus of research needs to be
59 expanded to consider additional limbic system tracts. It is also important to test whether alterations in
60 WM microstructure are common or distinct across males and females with CD.
61
62 An additional limitation of prior studies is that they used either tractography methods or a
63 characterization of WM diffusivity exclusively based on the diffusion tensor model. Although the
64 diffusion tensor model is most frequently used to reconstruct WM tracts and characterise diffusivity in
65 WM (Basser et al., 2000), this approach has several limitations. First, it is not well-suited for studying
66 complex fibre configurations such as crossing fibres, branching regions or intra-voxel combinations of
67 different tissue types (e.g., WM fibres and grey matter). Second, while FA is the most commonly used
68 index to quantify water diffusivity in studies using tensor-based models, it is calculated at a voxel level
69 and is determined by several microstructural and macrostructural features, such as myelination of WM
70 fibres, size and packing density of cells and number of crossing fibres (Vanderauwera et al., 2015).
71 Thus, partial volume effects (i.e., not fibre- or tissue -specific) can affect DTI indices (e.g., FA, RD),
72 and voxel-average diffusion MRI parameters such as FA, lack within-voxel single fibre population
73 specificity (Dell'Acqua et al., 2013; Raffelt et al., 2015). Novel non-tensor models such as constrained

4

74 spherical deconvolution (SD) have the potential to overcome these limitations and more accurately

75 characterise the underlying architecture of specific WM tracts (Dell'Acqua et al., 2010). In addition,

76 the hindrance-modulated orientational anisotropy (HMOA) index that can be derived using SD

77 algorithms provides greater sensitivity in terms of detecting microstructural changes in specific WM

78 tracts than FA (Dell'Acqua et al., 2013). Finally, most previous DTI studies included relatively small

79 samples - typically groups of 15 participants or fewer (Sethi et al., 2018; Finger et al., 2012; Haney-

80 Caron et al., 2014; Passamonti et al., 2012; Zhang, Gao, et al., 2014).

81

82 The present study addresses a number of these limitations, and extends previous findings by, first,

83 examining sex differences in the relationship between CD and WM microstructure. Second, by

84 examining two key limbic WM tracts overlooked in prior studies: the fornix and the cingulum bundles

85 - the retrosplenial (RSC), parahippocampal (PHC) and subgenual cingulum (SGC; Jones et al., 2013) -

86 as tracts plausibly involved in the pathophysiology of CD. Third, by enhancing statistical power and

87 the robustness of our results by substantially increasing the sample size compared to previous studies.

88 Finally, by employing a novel method – constrained SD. Recent studies have compared tensor versus

89 non-tensor models in clinical samples and suggested that the latter approach provides more accurate

90 and robust results (Auriat et al., 2015). However, to increase comparability with previous studies, we

91 also estimated indices of FA - the most widely-used parameter in previous structural connectivity

92 research.

93

94 We hypothesised that differences between CD and control groups would be most evident in limbic

95 tracts involved in socio-emotional processes (i.e., subgenual cingulum, retrosplenial cingulum, and UF)

96 in comparison with posterior and lateral limbic WM tracts (e.g., parahippocampal cingulum). We also

97 hypothesised that CD-related alterations in WM microstructure would be most evident in males (Zhang

98 et al., 2014). In addition, recent DTI studies have shown that individuals with CD and elevated callous-

99 unemotional (CU) traits may differ from those with low levels of CU traits in terms of WM

100 microstructural abnormalities (Sethi et al., 2018; Puzzo et al., 2017). Thus, we also investigated whether

101 CU traits contributed to the WM microstructural alterations observed in CD. We also tested for

102 correlations between WM measures and the grandiose-manipulative and impulsive-irresponsible

103 subdimensions of psychopathy and CD symptoms.

104 **Methods**

105 **Participants**

106
107 Participants for this study were recruited at four different sites involved in the Neurobiology and

108 Treatment of Female Conduct Disorder (FemNAT-CD; www.femnat-cd.eu) study - University of

109 Southampton, University of Birmingham, University Hospital Aachen, and University of Basel. All

110 participants and the majority of their parents underwent a diagnostic interview that was based on

111 DSM-IV criteria (the Kiddie-Schedule for Affective Disorders and Schizophrenia-Present and

112 Lifetime; Kaufman et al., 1997). At the UK sites, IQ was assessed using the two subtest form of the

113 Wechsler Abbreviated Scale of Intelligence (Wechsler, 1999) whereas the German version of the

114 Wechsler Intelligence Scale for Children (Wechsler, 2003) was used at the other sites. The t and

115 standard scores from all sites were transformed into z-scores and then combined to yield estimates of

116 full-scale IQ.

117 The Match program (Van Casteren and Davis, 2007) was used to select an IQ-, age- and gender-matched

118 sample from the subset of participants for whom diffusion MRI data were available (n=325). There are

119 dramatic changes in WM development across childhood and adolescence (Casey et al., 2008), thus we

120 excluded children aged 9-12 years (n=57; see Supplementary Material for more information). A total

121 sample of 200 adolescents (101 with conduct disorder (52 females) and 99 healthy controls (50 females)

122 was included in the present analyses – all aged 13-18 years. The Youth Psychopathic traits Inventory

123 (YPI; Andershed et al., 2002); a self-report questionnaire assessing overall psychopathic traits and sub-

124 dimensions of psychopathy, and the parent-report Inventory of Callous Unemotional traits (ICU; Essau,

125 Sasagawa and Frick, 2006); a standardized measure including callous, uncaring and unemotional

126 subscales, were used to assess psychopathic and callous-unemotional (CU) traits, respectively.

127 **Diffusion-weighted MRI data acquisition**

128

129 Diffusion-weighted MRI data were acquired with the following parameters: Repetition time (TR) =

130 8000ms (Achieva), 8800ms (Tim-Trio), 7500ms (Prisma); echo-time (TE) = 87ms (Achieva), 92ms

131 (Tim-Trio), 71ms (Prisma) and a bandwidth of 1633.3 Hz/Px (Achieva) or 1776 Hz/Px (Tim-Trio &

132 Prisma); echo-spacing = 0.75ms (Achieva), 0.73ms (Tim-Trio), 0.65ms (Prisma); slice thickness =

133 2.0mm; field of view (FOV) = 256 x 256 x 124mm; acquisition matrix = 128 x 128; voxel-size =

134 $2\times2\times2$mm; 62 contiguous axial slices (no slice gap). Images were acquired with diffusion gradients (b-

135 value=1500 s/mm²) applied in 64 non coplanar and non collinear directions and two b-value=0 (s/mm²)

136 volumes with reversed phase encoding (blip-up/blip-down), yielding pairs of images with distortions in

137 opposite phase-encode directions to enable accurate estimation and correction for susceptibility-

138 induced distortions.

139

140 **Pre-processing**

141

6

Datasets were corrected for head motion and eddy current distortions using FSL (Andersson and Sotiropoulos, 2016). Distortions in the magnetic field were estimated. The estimated field was subsequently used, together with all the diffusion data, to estimate eddy current-induced distortions and subject movement (Andersson and Sotiropoulos, 2016). Movement-induced signal dropout was identified and the lost signal was replaced by a non-parametric Q-space interpolation (Andersson et al., 2016).

Spherical deconvolution was calculated using the damped Richardson-Lucy algorithm (Dell'Acqua et al., 2010) with a fibre response parameter of α =1.5, 400 algorithm iterations, threshold parameters of 0.06, and a harmonic order of 8 (lmax=8). An absolute (0.1%) and relative (5%) threshold on the Fibre Orientation Distribution (FOD) amplitude were applied to exclude spurious local connections (Dell'Acqua et al., 2013).

Whole brain deterministic tractography was performed using a step size of 0.5mm with a limit set to display streamlines between 20 and 400 mm. The Euler algorithm was used to follow the orientation vector of least curvature (angle threshold of 45º). Spherical deconvolution and tractography analysis was performed using StarTrack software (https://www.mr-startrack.com/). Explore DTI was used for the tensor fit. Tensor-derived FA and HMOA values of WM microstructural organisation were exported to TrackVis. We report FA values in the present study for the purpose of increasing comparability with previous studies.

Delineation of Regions of Interest

TrackVis was used to reconstruct the fornix, cingulum bundle subdivisions and UF. Reconstruction of these tracts has previously been described (fornix and UF: (Stieltjes et al., 2013), and CB subdivisions: (Jones et al., 2013)). The Boolean logic (AND, and NOT gates) was employed to delineate the CB´s subdivisions, the fornix and the UF (Figure 1 shows the reconstruction for all of the limbic WM tracts).

Statistical analysis

Matlab_R2016 was used to carry out statistical analysis. Shapiro-Wilk tests were used to verify normality of HMOA and FA values across subjects.. Tract measures of HMOA and FA were analysed using a general linear model (GLM) to test for effects of diagnosis and sex-by-diagnosis interactions. The GLM included the following covariates which have been shown to be associated with WM microstructural integrity in adolescent studies: age (Asato et al., 2010), IQ (Dunst et al., 2014), and site (coded as binary fixed effect). Where significant sex-by-diagnosis interactions were found, we followed these up by comparing FA and HMOA values between CD and healthy control males, and between CD and healthy control females.

178

179 ADHD is a neurodevelopmental disorder that frequently co-occurs with CD, and previous DTI studies

180 have shown that comorbid ADHD strongly modulates WM effects (Wang et al., 2012). Thus, we

181 repeated the GLM analysis while adding current ADHD symptoms (i.e., those displayed in the last year)

182 as an additional covariate.

183

184 In addition, there is some evidence for structural differences between the childhood–onset (CO) and

185 adolescent-onset (AO) variants of CD (Fairchild et al., 2015). Accordingly, we used the same model to

186 compare these subgroups, to assess the validity of combining these subgroups in our main analysis.

187

188 The significance threshold was adjusted using the Benjamin–Hochberg false discovery rate (FDR:

189 q<0.05) correction for multiple comparisons across each parameter independently. Effect sizes for

190 diagnosis effects were calculated using Cohen's d and effect sizes for sex-by-diagnosis interactions

191 were expressed as partial eta-squared (ηp^2).

192 In cases where significant main effects of diagnosis were observed, we followed these up by running a

193 GLM analysis (only in the CD group), to test for associations between CD symptoms, psychopathy

194 (YPI total), dimensions of psychopathic traits (grandiose-manipulative, and impulsive-irresponsible

195 traits), CU traits (YPI subscale and ICU total), ICU subscales (callousness, uncaring, unemotional), and

196 measures of HMOA and FA. Lastly, given that the CD sample included many individuals with

197 comorbid ADHD, we also explored the relationship between ADHD symptoms and measures of

198 HMOA and FA. These correlational analyses were run in a mixed-sex CD group (males and females

199 with CD) as well as in each sex separately.

200

201 **Results**

202 **Demographic Variables**

203 Individuals in the CD group had significantly more CD, ODD, and ADHD symptoms than healthy

204 controls. They also scored higher in overall psychopathic traits, as well as callous-unemotional,

205 grandiose and manipulative, and impulsive and irresponsible subdimensions of psychopathy (Table 1).

206 There were no significant differences between males and females in the age-of-onset of CD (i.e.,

207 childhood-onset vs. adolescent-onset).

208

209 In terms of psychiatric comorbidity in individuals with CD, males and females differed only in rates of

210 substance abuse (M>F); there were no other significant differences between males and females. Finally,

8

211 there was an unequal sample distribution across the sites (see Supplementary Table 1). To address this
212 issue, we included site as a covariate of no interest.

213

214 **Tractography results**
215 There were no significant differences between the CO-CD and AO-CD subtypes in HMOA or FA in
216 any WM tract.

217

218 **Main effects of diagnosis**
219 Relative to controls, individuals with CD had lower HMOA in bilateral retrosplenial cingulum (RSC;
220 right: $t(190)=-2.22$, $p=0.03$, $d=0.10$; left: $t(190)=-2.27$, $p=0.02$, $d=0.16$), and lower FA in the right RSC
221 ($t(190)=-2.91$, $p=0.004$, $d=0.28$). However, after correcting for multiple comparisons, only the effect
222 on right RSC FA remained significant (pFDR=.03; Figure 2). There were no significant group
223 differences in HMOA or FA in any of the other limbic WM tracts.

224

225 **Sex-by-diagnosis interactions**
226 We observed sex-by-diagnosis interactions for HMOA in bilateral RSC (right: $t(190)=2.08$, $p=0.04$,
227 $\eta p^2=0.02$: left: $t(190)=1.99$, $p=0.05$, $\eta p^2=0.02$), and FA in right RSC ($t(190)=2.75$, $p=0.006$, $\eta p^2=0.04$).
228 All interactions followed the same pattern: males with CD showed lower values than male controls,
229 whereas females with CD showed higher values than female controls (Figure 3). However, only the
230 sex-by-diagnosis interaction for right RSC FA survived correction for multiple comparisons
231 (pFDR=.05). No other significant interaction effects were found in the other limbic tracts (see
232 Supplementary Table 2). Post-hoc analysis showed that relative to male controls, CD males had lower
233 HMOA in bilateral retrosplenial cingulum (RSC; right: $t(190)=-2.52$, $p=0.04$, $d=0.39$; left: $t(190)=-$
234 1.99, $p=0.04$, $d=0.37$) and lower FA in the right RSC ($t(190)=-2.91$, $p=0.01$, $d=0.47$). However, after
235 correcting for multiple comparisons, only the effect in right RSC FA remained significant (pFDR=.03).
236 There were no significant differences between female CD and control groups.

237

238 **ADHD comorbidity as a potential confound**
239 The main effects of diagnosis observed for FA in the right RSC ($p=0.03$) and for HMOA in bilateral
240 RSC (left: $p=0.05$: right: $p=0.05$) in CD versus healthy control males remained significant after
241 factoring out current ADHD symptoms. However, only the group difference in right RSC FA remained
242 significant (pFDR=0.03) after correcting for multiple comparisons. Moreover, significant main effects
243 of diagnosis emerged in the right UF when factoring out ADHD symptoms: participants with CD
244 showed lower FA ($t(189)=2.00$, $p=0.05$, pFDR=0.05), and HMOA ($t(189)=2.07$, $p=0.04$, pFDR=0.05;

245   Figure S1) relative to healthy controls. Unlike the findings for the RSC, this main effect of diagnosis in

246   the UF was not qualified by a significant sex-by-diagnosis interaction.

247

248   **Correlations between structural connectivity measures and CD symptoms, ADHD symptoms, and**

249   **psychopathic or callous-unemotional traits**

250

251   Within the CD sample, there was a positive correlation between current CD symptoms and right RSC

252   HMOA (r=.36, pFDR=0.02; Figure 4). There were no other significant correlations between CD,

253   ADHD symptoms, overall psychopathic traits, the subdimensions of psychopathy, CU traits or the ICU

254   subscales (Callousness, Uncaring, Unemotional) and measures of WM in other tracts.

255

256   As effects of diagnosis were found in males, but not in females with CD, we conducted correlational

257   analyses in males and female groups separately. A strong positive correlation between current CD

258   symptoms (r=.45, pFDR=0.002; Figure S2), and a negative correlation between current ADHD

259   symptoms (r= -.31, pFDR=0.03; Figure S3) and right RSC HMOA was found in the male CD group.

260   No effects of CU or psychopathic traits were observed in CD males. No significant correlations were

261   found between clinical symptoms or CU/psychopathic traits or subscales and measures of structural

262   connectivity in females with CD. Moreover, there were no significant sex-by-CD symptoms or sex-by-

263   CU/psychopathic traits interactions for either HMOA or FA.

264

265

266   **Discussion**

267   Abnormalities in the limbic system have been consistently implicated in the pathophysiology of CD

268   (Alegria et al., 2016; Raschle et al., 2015; Rogers and De Brito, 2016). We extended the DTI literature

269   by including female participants and a much larger sample than has been studied to date (N=200). This

270   allowed us to test whether females and males with CD show common or distinct alterations in limbic

271   WM microstructure. We also investigated limbic WM tracts beyond the UF and capitalised on recent

272   methodological advances in diffusion-weighted image processing by employing spherical

273   deconvolution (SD) models. This approach provides a more reliable estimation of multiple fibres

274   passing through a voxel with distinct orientations.

275

276   Our findings extend knowledge regarding alterations in limbic WM tracts in CD and support the

277   hypothesis that abnormalities in fronto-limbic tracts are involved in the pathophysiology of this

278   disorder. However, such abnormalities appear to be limited to males with CD – no such effects were

279   found in females. More specifically, only males with CD showed lower FA in the right RSC relative to

280   male controls. In fact, there was a suggestion that the opposite pattern was observed in females (females

281 with CD appeared to show higher FA and HMOA values relative to control females) – although this
282 was not statistically significant.
283
284 Previous DTI studies have found structural abnormalities in regions that overlap with the RSC. A recent
285 study using a similar approach to the present study (i.e., region of interest-based tractography)
286 investigated dorsal and ventral cingulum WM microstructure in male youths with CD (Sethi et al.,
287 2018). Lower RD values were observed in bilateral dorsal cingulum in the CD group relative to controls
288 (Sethi et al., 2018). FA values normally increase when RD decreases, and the opposite pattern seems
289 associated with myelin loss and axonal abnormalities (Harsan et al., 2006). Although the anatomical
290 delineation of the cingulum bundle differed between the two studies (i.e., dorsal and ventral in Sethi et
291 al. versus retrosplenial, parahippocampal and subgenual cingulum in the present study), the dorsal part
292 of the cingulum overlaps most closely with the RSC tract compared to the other cingulum bundles –
293 thus the findings are congruent in terms of location, but not in the direction of the effects. In addition,
294 the Sethi et al. (2018) study differs from the present study in the use of tensor-based models versus non-
295 tensor models.
296
297 The RSC is composed of fibres that connect the medial prefrontal cortex, dlPFC, ACC, PCC, medial
298 temporal lobe, and angular gyrus together (Jones et al., 2013). These regions have been associated with
299 social-emotional processing, self-reflection, executive functions and moral decision-making. They are
300 key nodes of the default mode network (DMN) that is responsible for self-referential processing (Leech
301 et al., 2012). Previous studies investigating DMN connectivity in youths with CD have reported reduced
302 connectivity between core DMN regions including the medial PFC, PCC, precuneus and superior
303 temporal gyrus, relative to controls (Broulidakis et al., 2016; Zhou et al., 2016). It has been proposed
304 that DMN dysfunction in CD may reflect delays in the development of brain circuits linked to self-
305 awareness, regulating emotions, moral judgments and future planning (Zhou et al., 2015). Impairments
306 in these processes have been reported in CD (e.g. White et al., 2014). The RSC connects core regions
307 that make up the DMN. Thus, the abnormal functional connectivity of the DMN observed in previous
308 studies may have a structural basis in altered RSC connectivity.
309
310 Although group differences in FA in the UF only became significant after controlling for comorbid
311 ADHD symptoms, our results are in contrast to findings reported by Zhang et al. (2014). We did not
312 observe any sex-by-diagnosis interactions in this WM tract. Both males and females with CD appeared
313 to be equally affected in terms of showing lower UF FA. However, in line with Zhang et al. (2014), we
314 also observed sex differences in the RSC tract in youths with CD. Males with CD showed lower FA
315 (and HMOA at an uncorrected level) relative to sex-matched healthy controls, whereas there were no
316 significant differences between CD and control females.

11

317   Previous DTI studies of CD have observed higher FA values in male-only samples, suggesting
318   accelerated maturation in individuals with CD. Here, we observed lower FA in males with CD
319   compared to male controls. Although the results observed here were in a previously unstudied tract, it
320   suggests that WM maturation is delayed in males with CD. Delayed maturation of WM is associated
321   with poor inhibitory control (Simmonds et al., 2014) - a key feature of CD.

322

323   Furthermore, our correlational analyses showed that CD symptoms were significantly (positively)
324   correlated with HMOA of the right RSC tract in males, but not females. Therefore, the present study
325   provides new evidence for sex differences in the neurobiological basis of CD – RSC WM abnormalities
326   were observed in males but not females. We also observed a significant negative correlation between
327   ADHD symptoms and HMOA in the right RSC tract in males but not females, indicating that ADHD
328   comorbidity may have influenced the differences between CD and control males in the RSC. This is of
329   significance due to the substantial overlap of ADHD and CD, and symptom dimensions related to
330   ADHD such as impulsivity and hyperactivity have been associated with the development of antisocial
331   behaviour in childhood (Barkley et al., 2004).

332   Several neuropsychological studies investigating aspects of executive functioning (i.e., assessing
333   inhibition/attention and decision-making), are consistent with our findings by showing divergent results
334   in males and females with CD. Males with CD exhibit deficits in reversal learning (Herpertz et al.,
335   2008) and differ in terms of decision-making (e.g., making more risky choices) relative to control males,
336   whereas CD females do not differ from control females (Sidlauskaite et al., 2017). In addition, our
337   finding of a sex-by-diagnosis interaction in the RSC highlights the importance of taking sex into account
338   when studying the neurobiology of CD, and the problems that might arise when combining males and
339   females with CD in the same group (Smaragdi et al., 2017). Future studies should investigate the
340   functional consequences of altered RSC structural connectivity in males and females with CD by
341   employing resting state functional connectivity methods, and by using neuropsychological tasks tapping
342   decision-making and empathic processes in the same sample.

343

344   **Strengths and limitations**

345

346   The strengths of this study include the investigation of additional limbic WM tracts by using a more
347   comprehensive approach – SD tractography. The main benefit of this approach is to resolve fibre-
348   crossing issues. In addition, SD techniques improve the accuracy of fibre tracking compared to models
349   based on the diffusion tensor alone (Dell'Acqua et al., 2010). Secondly, the comparatively large sample
350   size in the present study (N=200), which included males and females with and without CD, allowed us,
351   for the first time, to comprehensively investigate sex differences in the relationship between CD and
352   structural connectivity. Another strength is the fact that the CD group was assessed using standardised,

353   semi-structured interviews based on DSM-IV criteria as well as obtaining detailed information about

354   comorbid disorders and accounting for ADHD comorbidity in our statistical analyses.

355

356   However, our study also had several limitations. First, the sample ranged in age from 13-18 years. The

357   CD and control groups did not differ in age; however, age is known to have an important effect on white

358   matter development. Thus, we included age as a covariate of no interest in all analyses. Second, the sex

359   distribution across the sites was uneven (more girls were tested at some sites than others), and although

360   quality control procedures were performed prior to starting data acquisition (e.g., matching acquisition

361   parameters and going through a site qualification process), combining data from different sites and

362   scanner manufacturers (Phillips and Siemens) may introduce unintended variability. However, to

363   reduce the impact of this variability, all analyses included site as a covariate of no interest. Finally,

364   although we used SD methods to reconstruct the WM tracts, indices of FA were derived from tensor-

365   based models fitted to b=1500 diffusion-weighted data and projected onto the SD-derived tracts. Hence

366   there is a potential source of variability in terms of comparing the present FA measures with those

367   reported in previous studies, although several earlier studies adopted a similar approach (e.g.,

368   Christiansen et al., 2016, Rojkova et al., 2016).

369

370   In conclusion, we found that male adolescents with CD differed from healthy controls in retrosplenial

371   cingulum white matter microstructure – showing lower FA and HMOA values in this tract. This effect

372   was not seen in females with CD. These differences in structural connectivity may help explain sex

373   differences in CD and its clinical presentation. Given the overlap of the RSC tract with brain regions

374   that constitute the DMN, and its role in connecting these regions together, future studies should

375   investigate whether there are sex differences in DMN functional connectivity in CD. This would

376   improve our understanding of the pathophysiology of CD and could lead to improved diagnosis and

377   treatments for both sexes.

MDD	11(21)		4(8)			X^2= 3.36 (0.06)	
Alcohol abuse	1(2)		4(8)			X^2=2.08 (0.14)	
Alcohol dependence	0		0				
Substance abuse	1(2)		7(14)			X^2=5.28 (0.02)	
Substance dependence	1(2)		5(10)			X^2=3.09 (0.07)	
Generalized Anxiety Disorder	7(14)		2(4)			X^2= 2.73 (0.09)	

Note: CD, Conduct disorder; HC, healthy controls; ADHD, attention-deficit/hyperactivity disorder; ODD, Oppositional defiant disorder; PTSD, post-traumatic stress disorder; MDD, major depressive disorder; YPI, Youth Psychopathic traits Inventory; ICU, Inventory of Callous Unemotional traits. # Number of traumatic events were estimated from the K-SADS-PL interview data.
Figure 1 Tractography reconstruction for all limbic white matter tracts. A. Coronal tractography reconstruction of the subgenual cingulum (SGC): a) First sphere of interest placed 5 slices anterior to the mid-sagittal view. b) Target sphere placed 3 slices anterior to the genu of the corpus callosum. c) Final reconstruction of the SGC. **B. Coronal tractography reconstruction of the retrosplenial cingulum (RSC):** a) First sphere of interest placed 5 slices posterior to the mid-sagittal view. b) Target sphere placed 3-4 slices above the splenium. c) Final reconstruction of the RSC. **C. Coronal tractography reconstruction of the parahippocampal cingulum (PHC).** a) First sphere of interest placed behind the splenium. b) Target sphere placed 3-4 slices below sphere A. c) Final reconstruction of the PHC. **D. Coronal tractography reconstruction of the uncinate fasciculus (UF):** a) First sphere of interest placed in the fronto-temporal junction. b) Target sphere placed at the temporal pole. c) Final reconstruction of the UF. **E. Coronal tractography reconstruction of the fornix.** a) One coronal sphere placed in the body of the fornix. b) Final reconstruction of the fornix.
Figure 2. Main effects of diagnosis on fractional anisotropy of the right retrosplenial cingulum. Group differences are significant at p<.05, False Discovery Rate correction. Error bars show 95% confidence intervals of the mean. HC, healthy control; CD, Conduct Disorder; FA, fractional anisotropy
***Fi*gure 3. Sex by diagnosis interactions in the retrosplenial cingulum tract**. A) Sex by diagnosis interaction on fractional anisotropy values in the right retrosplenial cingulum, which was significant at pFDR=0.05. B) 3D reconstruction of the retrosplenial cingulum tract. C) Sex by diagnosis interactions in the Hindrance Modulated Orientational Anisotropy of the right retrosplenial cingulum. D) Sex by diagnosis interactions in the Hindrance Modulated Orientational Anisotropy of the left retrosplenial cingulum. Error bars show 95% confidence intervals of the mean. HC, healthy control; CD, Conduct Disorder.
Figure 4. Association between CD symptoms and hindrance modulated orientational anisotropy (HMOA) in the right retrosplenial cingulum in the CD group.
There was a significant positive correlation between CD symptoms and HMOA values in the right retrosplenial cingulum tract.
