Psychosis continuum
Depression
COVID-19

ABSTRACT

Loneliness is common in psychosis and occurs along a continuum. Here we investigate inter-relationships between loneliness, three-dimensional schizotypy, and depressive symptoms before and during the COVID-19 pandemic.

The sample included 507 university students (48.3% participated before and 51.7% during the COVID-19 pandemic) who completed the Multidimensional Schizotypy Scale-Brief, the Counseling Center Assessment of Psychological Symptoms depression scale and the University of California, Los Angeles Loneliness Scale. Schizotypy and depression scores were regressed onto loneliness individually and in multiple regressions.

The cohorts did not differ in any of the schizotypy domains (all $p > .29$). Depressive symptoms ($p = .05$) and loneliness ($p = .006$) were higher during the pandemic than before. Across cohorts, loneliness was significantly associated with positive ($\beta = 0.23, p < .001$), negative ($\beta = 0.44, p < .001$), and disorganised schizotypy ($\beta = 0.44, p < .001$), and with depression ($\beta = 0.72, p < .001$). Schizotypy together explained a significant amount of variance in loneliness ($R^2 = 0.26$), with significant associations with positive ($\beta = -0.09, p = .047$), negative ($\beta = 0.31, p < .001$) and disorganised schizotypy ($\beta = 0.34, p < .001$). When depression was included ($\beta = 0.69, p < .001$), only positive ($\beta = -0.09, p = .008$) and negative schizotypy ($\beta = 0.22, p < .001$) significantly predicted loneliness.

When all schizotypy dimensions and depression were considered together, only negative schizotypy and depression significantly predicted loneliness. Loneliness and depressive symptoms were higher during the pandemic, but this did not relate to cohort differences in schizotypy.

1. Introduction

Loneliness is defined as a distressing experience occurring when the quality or quantity of social relationships is perceived as insufficient to fulfil the social need (Hawkley, 2018). It refers to a subjective perception of social relations that is not necessarily related to objective social isolation. While often a transient experience, loneliness can become chronic. Initial feelings of loneliness are believed to function as a biological survival mechanism, guiding individuals to adjust their behaviours towards pro-sociality (Cacioppo et al., 2006). Through the unpleasant feeling, often described as the social equivalent of hunger or physical pain (Cacioppo and Hawkley, 2005), individuals are alarmed of their threatened social network and encouraged to tend to their social relationships. This mechanism might enhance the motivation to approach social situations and ensure that individuals stay part of the

social flock (Cacioppo et al., 2006). However, loneliness also appears to have negative consequences, such as negative attributional biases, which increase an individual's focus on social threats and rejective social content. It has been shown that lonely people pay more visual attention to socially threatening stimuli (Bangee et al., 2014), and that they are quicker to differentiate socially threatening from non-threatening stimuli (Cacioppo et al., 2016). This enhanced attention to negative social stimuli can lead to a vicious cycle of loneliness, in which negative attributional biases enforce the perception of social threats, making it difficult to trust and to obtain social relationships (Cacioppo and Hawkley, 2005).

Given its implications for social threat perception, loneliness might be particularly problematic for individuals with schizophrenia, who often experience paranoia, which may be aggravated with increased social threats. Loneliness constitutes a significant problem in

schizophrenia (Eglit et al., 2018; Lim et al., 2018; Michalska da Rocha et al., 2018). An estimated 80% of people with schizophrenia experience loneliness, which is markedly more than the estimate of 35% in the general population (Stain et al., 2012). Previous research has linked loneliness to both onset (Chau et al., 2019; Hoffman, 2007), and maintenance (Kwapil et al., 2012; Lim et al., 2018) of psychotic symptoms. Kwapil et al. (2012) suggested that the positive symptom dimension is characterised by an ambivalent need for social interactions; when alone, individuals with positive symptoms desire social company, but when with others they desire to be alone. Importantly, the desire to be alone was mostly a result of anxious fears of negative evaluation – and not due to lack of pleasure in social interactions. As loneliness constitutes the discrepancy between preferred and actual social interactions (Hawkey, 2018), it is likely that the ambivalent social need within the positive dimension inhibits optimal social functioning and confers specific vulnerability to loneliness. In accord with this, loneliness has been linked to paranoia in both clinical and non-clinical samples (Chau et al., 2019; Lamster et al., 2017a; Lamster et al., 2017b), and to social anxiety, depression, and even the onset of positive psychotic symptoms in healthy individuals (Le et al., 2019; Lim et al., 2016). On the other hand, the negative symptoms of schizophrenia might be associated with a complete loss of interest in social interactions, due to low social motivation (Rabinowitz et al., 2012; Robertson et al., 2014). However, as negative symptoms are characterised by avolition, anhedonia and asociality (American Psychiatric Association, 2013), contributing to a general disinterest in social interactions (Kwapil et al., 2012), it seems intuitive that those who experience more negative symptoms might be less prone to loneliness. In line with this, social anhedonia has been linked to a higher preference for solitude and it has been argued that the need to belong has gone awry in the socially anhedonic (Silvia and Kwapil, 2011).

Research on loneliness and psychotic symptomatology has made use of the psychosis continuum, ranging from subclinical schizotypal traits to full-blown clinical psychosis (Barrantes-Vidal et al., 2015; Kwapil and Barrantes-Vidal, 2015). Schizotypy is thought to reflect the vulnerability for schizophrenia, implying shared underlying etiology (Barrantes-Vidal et al., 2015; Kwapil and Barrantes-Vidal, 2015; Lenzenweger, 2018; Meehl, 1962), and thus representing a useful construct for modeling schizophrenia. Studies examining loneliness across the psychosis continuum have found stable associations with positive and negative schizotypal traits (Badcock et al., 2016; Chau et al., 2019; Le et al., 2019; Michalska da Rocha et al., 2018). However, research has largely neglected the disorganised symptom dimension (Kemp et al., 2018; Kwapil et al., 2020; Nelson et al., 2013). Disorganised symptoms comprise cognitive aspects and include communication and attention difficulties which may hinder appropriate social communication. Furthermore, impairments in social cognitive processes (e.g., mentalising, emotion recognition, and social perception) have been linked to severity of disorganised symptoms (de Sousa et al., 2019), which may complicate the ability to interpret social situations. Disorganised symptoms have been found to predict social functioning impairments in both occupational and leisure settings in at-risk psychosis patients (Eslami et al., 2011). Therefore, it seems plausible that disorganised symptoms may contribute to loneliness. Conversely, it is possible that loneliness confers a risk for disorganised symptoms, as suggested by longitudinal studies linking loneliness to subsequent cognitive decline (Hannemann et al., 2020; Lara et al., 2019; Zhou et al., 2019). Due to the heterogeneity of schizotypy, the degree to which the different symptom dimensions link to loneliness is important. However, more research is needed to establish the associations between loneliness and the different schizotypy dimensions, in particularly the disorganised dimension.

The ongoing corona-virus disease (COVID-19) pandemic has demonstrated the impact of reduced social interactions on mental health. People were isolated from social and occupational settings, and some have had to isolate due to risk of contracting the disease. Social distancing measures had a noticeable toll on mental health (Esteves

et al., 2021; Jia et al., 2020; Loades et al., 2020; Savage et al., 2020). A recent review by the COVID-19 Mental Disorders Collaborators (Santomauro et al., 2021) has estimated that the prevalence of major depressive disorder has increased by 27.6%, while anxiety disorders increased by 25.6% globally. The pandemic has offered a natural opportunity for examining the relationship between loneliness and schizotypy (Daimer et al., 2021). We therefore investigated the association between loneliness and positive, negative, and disorganised schizotypy before and during the pandemic.

We hypothesized that loneliness would be associated with all three dimensions of schizotypy. Based on previous associations between paranoia and loneliness, as well as anxious avoidance of social situations despite a desire to engage, positive schizotypy was expected to be positively associated with loneliness. Negative schizotypy was expected to be negatively associated with loneliness, due to suggestions of a higher preference for solitude, diminished need to belong and low social motivation. Furthermore, we expected a positive association between disorganised schizotypy and loneliness, due to hypothesized difficulties with adequate responding to social cues. To understand the relationship between loneliness and negative schizotypy, it is important to acknowledge the overlap between negative and depressive symptoms. Symptoms including amotivation, avolition, anhedonia and anergia are thought to occur within both domains (Krynicky et al., 2018) and constitute a conceptual overlap which makes it difficult to distinguish between depressive and negative symptoms. Also, loneliness has been associated with depression in previous research (e.g., (Erzen and Çikrikci, 2018; Qualter et al., 2010)). Therefore, we included a measure of depressive symptoms to account for the overlap with negative schizotypy.

2. Method

2.1. Sample

The sample consisted of 507 students from City University of London (90.3% females, 9.3% males, and 0.4% others), aged 17–54 ($M = 19.75$, $SD = 3.62$). Data for 245 participants (48.3%) was collected in between November and January 2020 (before the pandemic), while data for the remaining 262 (51.7%) participants was collected between November and January 2021 (during the pandemic). Participants were recruited through a university call conducted through email, campus news and social media. Questionnaires were presented online using the Qualtrics software. Participants were required to be above 17 years old and fluent in English. All participants gave informed consent prior to participation. This study was approved by the City University of London Psychology Ethics Committee.

2.2. Measures

2.2.1. Schizotypal traits

The Multidimensional Schizotypy Scale-Brief (MSS-B) (Gross et al., 2018), was used to assess positive, negative, and disorganised schizotypy. The scale comprises 38 questions of which 13 items measure positive, 13 negative, and 12 disorganised traits. Participants rate each question as either (1) “True” or (0) “False”, and a higher score indicates higher trait-schizotypy. All three subscales showed good internal consistency: positive $\alpha = 0.79$, negative $\alpha = 0.74$ and disorganised $\alpha = 0.89$.

2.2.2. Loneliness

Loneliness was measured using the University of California, Los Angeles (UCLA) Loneliness Scale Version 3 (Russell, 1996). The scale comprises 20 items. Participants rate each question of a scale from 1 (*never*) to 2 (*often*), and a higher total score indicates higher loneliness. The UCLA scale showed good internal consistency in the current sample $\alpha = 0.90$.

* Significant at $p < .05$.

2.2.3. Depression

The Counseling Center Assessment of Psychological Symptoms (CCAPS-62) was used to measure depression (Locke et al., 2011). The depression subscale includes 13 items such as “I feel worthless” and “I have thoughts of ending my life” for which participants respond on a 5-point Likert scale ranging from 0 (not at all like me) to 4 (extremely like me). The CCAPS-62 depression subscale showed good internal consistency in the current sample $\alpha = 0.85$.

2.2.4. Statistical analyses

Statistical analyses were conducted using SPSS 27. Independent sample t -tests were used to investigate differences in MSS-B, UCLA, and CCAPS-62 depression scores between cohorts, i.e. before (*pre-COVID-19*) and during the pandemic (*during COVID-19*). Regression analyses were conducted on (1) positive schizotypy and loneliness, (2) negative schizotypy and loneliness, (3) disorganised schizotypy and loneliness, and (4) depressive symptoms and loneliness. Interaction terms between cohort and the three schizotypy dimensions and depression were added to the regression models to examine whether the relationships differed between cohorts. Finally, all schizotypy dimensions and depression were entered in a multiple regression analysis to examine their unique contribution to loneliness. We report standardized regression coefficients. Intercorrelations between all variables are reported.

Table 2
Intercorrelations, multicollinearity statistics and internal consistency for all scales.

	Multicollinearity (Tolerance, VIF)	Internal consistency (α)	1	2	3	4	5
1. Positive schizotypy	0.65 (1.55)	0.79	1				
2. Negative schizotypy	0.71 (1.42)	0.74	0.42**	1

** Significant at $p < .001$.

3. Results

3.1. Sample characteristics

Sample characteristics are displayed in Table 1. Participants showed higher loneliness [$t(504) = -2.78, p = .006$], and depressive symptoms [$t(501) = -1.97, p = .049$], during compared to before the COVID-19 pandemic. There were no significant cohort differences in positive $t(492) = -1.05, p = .29$, negative [$t(492) = -1.01, p = .31$], or disorganised schizotypy [$t(492) = -0.59, p = .55$].

3.2. Relationships between loneliness and schizotypy

Intercorrelations between all variables are reported in Table 2. Simple regression analyses showed that loneliness was significantly associated with all three schizotypy dimensions, most strongly with negative [$\beta = 0.44, t(493) = 10.87, p < .001, 95\% \text{ CI } (0.36-0.52)$, Fig. 1], and disorganised schizotypy [$\beta = 0.44, t(493) = 10.90, p < .001, 95\% \text{ CI } (0.36-0.52)$, Fig. 1], and to a lesser extent with positive schizotypy [$\beta = 0.23, t(493) = 5.22, p < .001, 95\% \text{ CI } (0.14-0.32)$, Fig. 1]. To explore whether the strength of the relationships between loneliness and schizotypy varied between cohorts, interactions between the three schizotypy dimensions, depression, and loneliness were added to the models. All interactions were non-significant (positive schizotypy [$\beta = 0.05, t(493) = 0.58, p = .57$], negative schizotypy [$\beta = 0.07, t(493) = 0.96, p = .34$], disorganised schizotypy [$\beta = -0.01, t(493) = -0.07, p = .95$], see Table 3 and Fig. 2). Therefore, for the multiple regression analysis cohorts were grouped together. The multiple regression analysis modelled the relationship between loneliness and all three schizotypy dimensions. Schizotypy explained a significant amount of variance in loneliness ($F(3,493) = 58.43, p < .001, R^2 = 0.26, R^2_{\text{Adjusted}} = 0.26$). Negative schizotypy [$\beta = 0.31, t(493) = 6.72, p < .001, 95\% \text{ CI } (0.21-0.39)$], disorganised schizotypy [$\beta = 0.34, t(493) = 6.69, p < .001, 95\% \text{ CI } (0.24-0.44)$], and positive schizotypy [$\beta = -0.09, t(493) = -1.99, p = .047, 95\% \text{ CI } (-0.19-0.01)$] significantly predicted loneliness.

3.3. Relationships between loneliness, schizotypy and depression

Simple regression analysis showed a significant association between depression and loneliness [$\beta = 0.72, t(502) = 23.33, p < .001, 95\% \text{ CI } (0.66-0.78)$, Fig. 1]. The interaction between cohort year and depression was not significant [$\beta = -0.09, t(499) = -1.21, p = .27$]. Therefore, for the multiple regression analysis cohorts were grouped together. The model included loneliness, all three schizotypy dimensions and depression. Schizotypy and depression explained a significant amount of variance in loneliness ($F(4,493) = 158.25, p < .001, R^2 = 0.56, R^2_{\text{Adjusted}} = 0.56$). Depression was the strongest predictor of loneliness, [$\beta = 0.69, t(493) = 18.37, p < .001, 95\% \text{ CI } (0.62-0.77)$]. Positive schizotypy [$\beta = -0.09, t(493) = -2.65, p = .008, 95\% \text{ CI } (-0.17 - -0.03)$] and negative schizotypy [$\beta = 0.22, t(493) = 6.19, p = .001, 95\% \text{ CI } (0.15-0.29)$] also significantly predicted loneliness. Disorganised schizotypy [$\beta = -0.03, t(493) = -0.62, p = .53, 95\% \text{ CI } (-0.11-0.06)$] no longer predicted loneliness significantly.

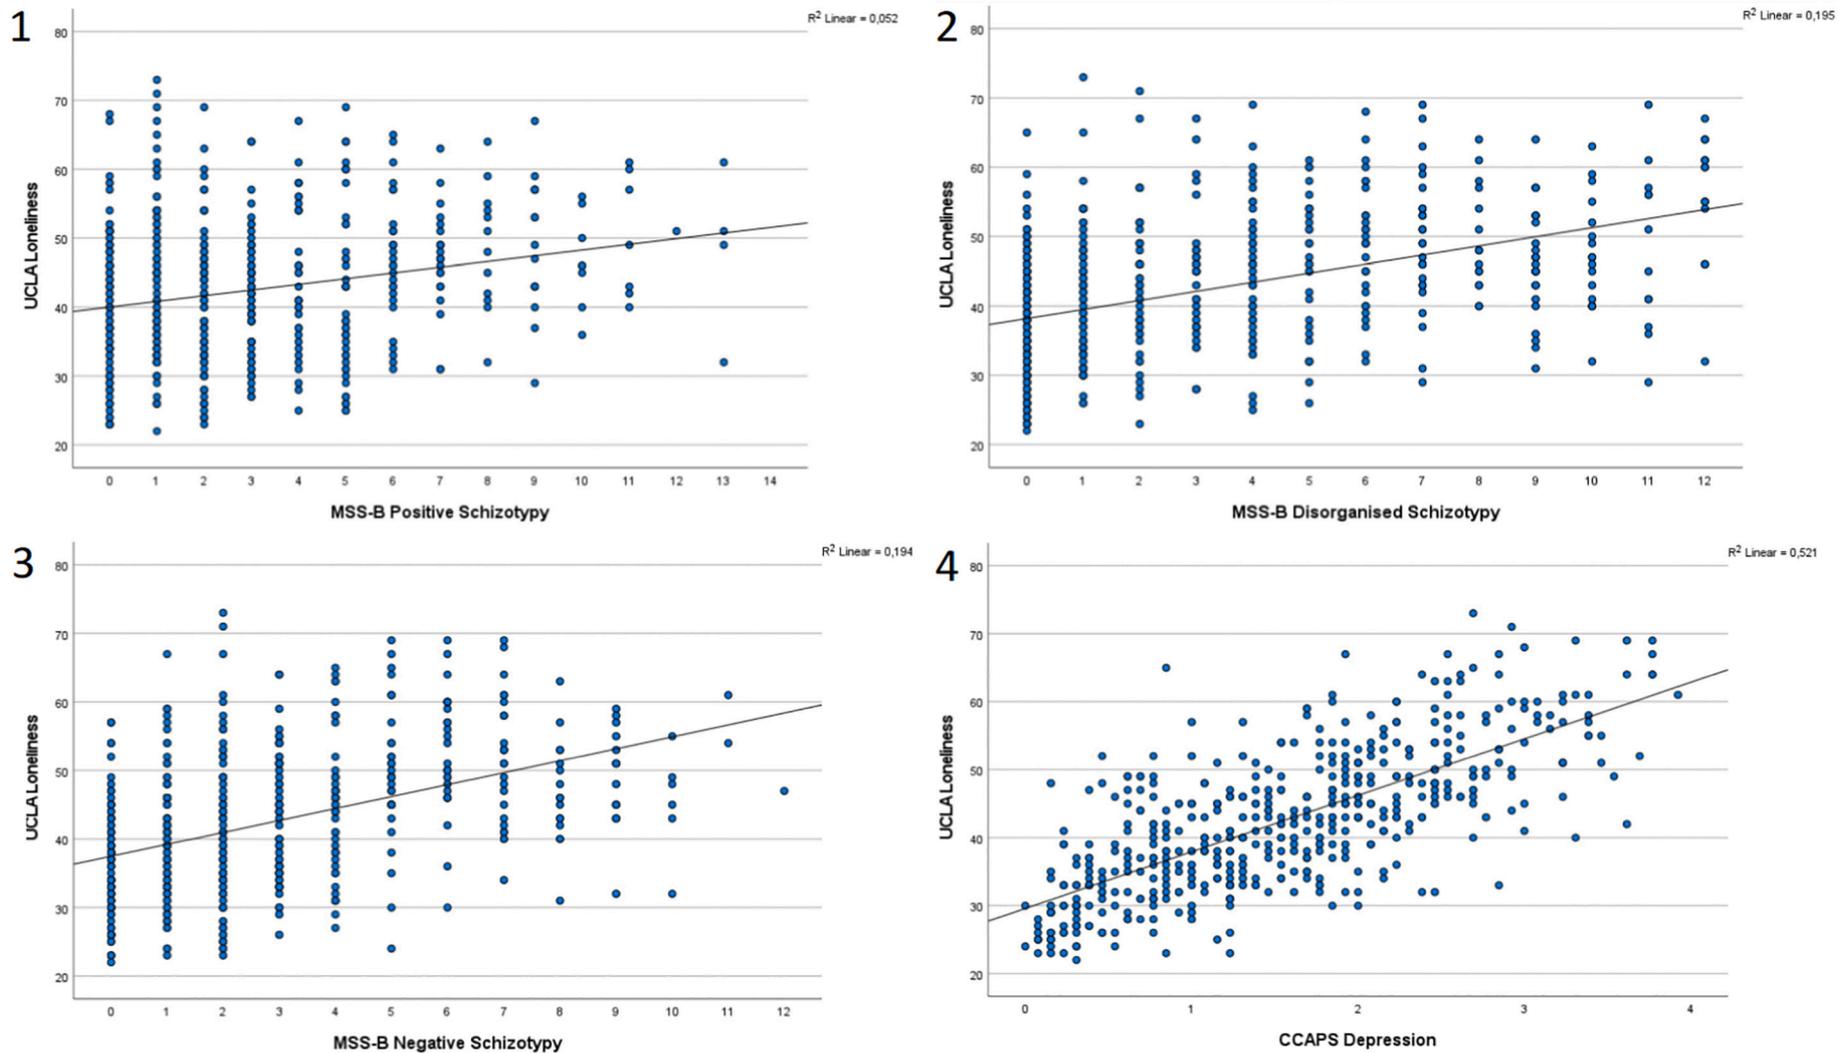

Fig. 1. Relationship between scores on the University of California (UCLA) loneliness scale and 1) positive, 2) disorganised, 3) negative schizotypy (MSS-B) and 4) depression (CCAPS).

Table 3
Regression of schizotypy on loneliness by cohort.

Dependent variable: UCLA Loneliness	Pre-COVID cohort		During COVID cohort	
	β (95% CI)	p	β (95% CI)	p
MSS-B				
Positive schizotypy	0.20 (0.08–0.32)	0.002	0.25 (0.12–0.37)	<0.001
Negative schizotypy	0.39 (0.28–0.51)	<0.001	0.47 (0.36–0.58)	<0.001
Disorganised schizotypy	0.44 (0.33–0.55)	<0.001	0.43 (0.32–0.54)	<0.001
CCAPS depression	0.76 (0.66–0.83)	<0.001	0.68 (0.59–0.77)	<0.001

4. Discussion

This study investigated the relationship between loneliness and positive, negative, and disorganised schizotypy in two cohorts of students prior to and during the COVID-19 pandemic. All schizotypy domains were individually associated with loneliness. In contrast to our hypothesis the strongest effects were present for negative and disorganised schizotypy. When all three domains were included in the model, the association with positive schizotypy reversed. When depression was accounted for, negative schizotypy remained a significant contributor to loneliness, thus highlighting negative schizotypy as a potential risk factor for loneliness. Disorganised schizotypy was no longer significantly related to loneliness. We found higher levels of loneliness and depressive symptoms in participants who completed the study during the pandemic, supporting findings of others (Esteves et al.,

2021; Jia et al., 2020; Killgore et al., 2020; Li et al., 2020; Palgi et al., 2020). However, this was not dependent on the level of schizotypy, which did not differ between cohorts.

4.1. The role of schizotypy in loneliness

In line with a proposed relationship between psychosis proneness and loneliness (Chau et al., 2019; Hoffman, 2007; Lim et al., 2018), we found significant individual relationships between higher scores on the three dimensions of schizotypy and loneliness. Notably, the largest effect sizes occurred for negative and disorganised schizotypy, underlining the importance of cognitive disorganisation and social motivation with respect to perceived social isolation. The positive association between disorganised schizotypy and loneliness is in line with previously established links, where disorganised schizotypy has been associated with greater emotional ambivalence, communication disturbances, increased reactivity to negative affect, lower cognitive control (Kerns, 2006; Kerns and Becker, 2008; Minor and Cohen, 2010), and social functioning impairments in individuals at-risk for psychosis (Eslami et al., 2011). Indeed, the ability to self-regulate thoughts, emotions and behaviour is thought to be vital for successful social functioning (Hawkley and Cacioppo, 2010). Findings that planning and working memory functions predict loneliness in elderly (Sin et al., 2021) lend further support to this. Thus, disorganisation may affect the ability to follow conversations and interact in socially appropriate ways, which in turn may foster loneliness. Conversely, it is also possible that loneliness contributes to disorganised schizotypy, for example by accelerating cognitive decline, which has previously been linked to loneliness in older adults (Boss et al., 2015; Lara et al., 2019; Tilvis et al., 2004). Several longitudinal studies have found associations between loneliness and decreased cognitive function at follow-up (Hannemann et al., 2020; Lara et al.,

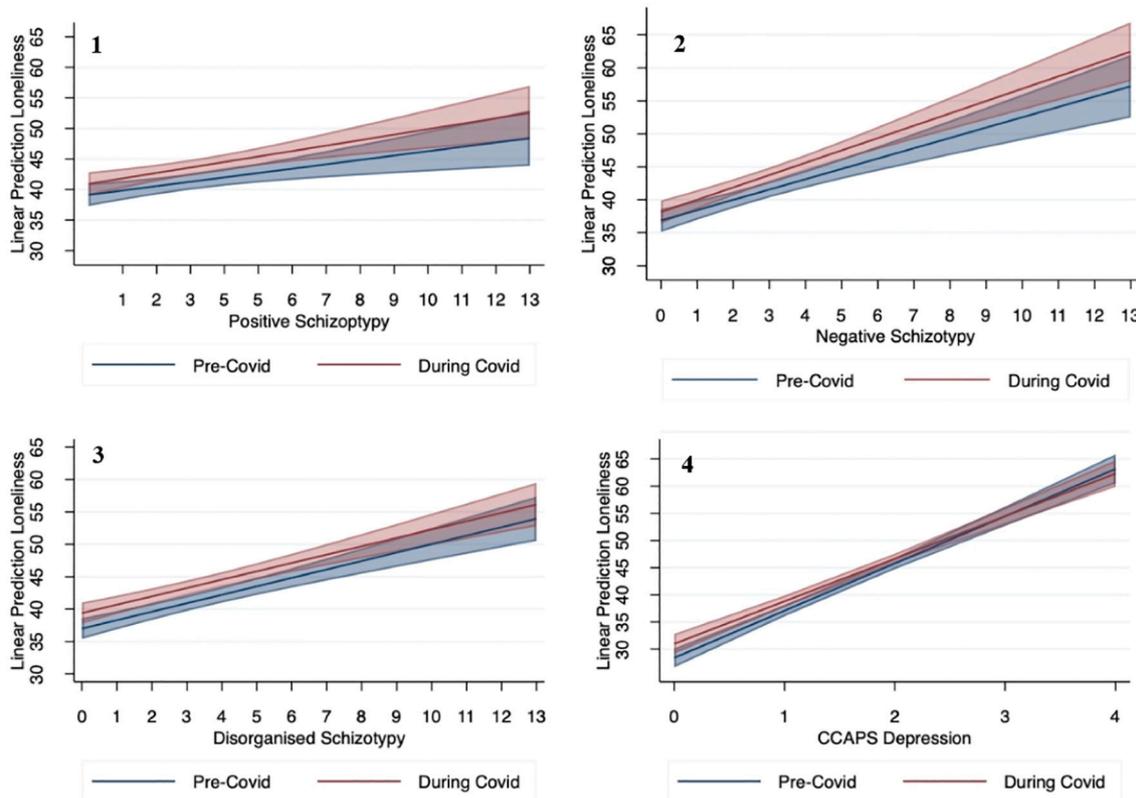

Fig. 2. Linear regression of schizotypy and depression on University of California (UCLA) loneliness scores for the pre-COVID-19 (blue) and during COVID-19 cohort (red) with 95% confidence intervals. (1) Multidimensional Schizotypy Scale-Brief (MSS-B) positive schizotypy, (2) MSS-B negative schizotypy, (3) MSS-B disorganised schizotypy, and (4) Counseling Center Assessment of Psychological Symptoms (CCAPS) depression. Overlap of confidence intervals is represented by the shaded middle area.

2019; Zhou et al., 2019), but mechanisms remain largely unknown (Kidambi and Lee, 2020). However, in the current sample of younger individuals the findings do not seem to support the notion that loneliness is causally related to disorganised schizotypy, given the significantly higher levels of loneliness in the face of stable levels of disorganised schizotypy across cohorts. The current data is cross-sectional and the results should be interpreted with caution. Longitudinal and experimental investigations are needed to investigate this question further.

Given that negative schizotypy is characterised by avolition, anhedonia and asociality (Kwapil et al., 2018), which may contribute to a general disinterest in social interactions (Silvia and Kwapil, 2011), it was expected to constitute a lower social need and a higher preference for solitude. In line with this negative symptoms have been established as important predictor of social functioning in chronic psychosis (Kaneko, 2018; Strauss et al., 2012; Weinberg et al., 2009), and in at-risk populations (Corcoran et al., 2011; Schlosser et al., 2015). Our finding that higher negative symptoms are related to higher loneliness was unexpected and suggests that negative symptoms do not change perceived ideals of social interactions (e.g., wanting to interact socially with friends). Alternatively, and in line with a possible relationship between the negative symptom dimension and salience (Chun et al., 2019), a lack of reward associated with negative symptoms may constitute a vulnerability for loneliness, rather than a diminished social need (Chun et al., 2019; Kwapil et al., 2012). That is, negative symptoms may diminish the rewarding effects of social interactions while leaving the need for social interaction unaffected. If increased schizotypy can be explained by attenuated expected pleasure (motivation) or attenuated pleasure derived from social interactions, conventional anti-loneliness strategies might not be effective in reducing loneliness in this population (Bessaha et al., 2020).

A further possible explanation for the link between higher loneliness and negative schizotypy is that negative schizotypy overlaps with depression (Matthews et al., 2016). Social disinterest, low social motivation and apathy are shared core characteristics (Edwards et al., 2019). We found the strongest association between loneliness and the CCAPS-62 depression subscale. Other research in university students with high and low schizotypy found that the diminished pleasure and motivational deficits, which are characteristic of the negative schizotypy dimension (Silvia and Kwapil, 2011), were fully mediated by depressive symptoms (Campellone et al., 2016). Importantly, in our study the strength of the association between negative schizotypy and loneliness was slightly reduced, but negative schizotypy remained a significant predictor of loneliness when depressive symptoms were accounted for. Thus, the relationship between negative schizotypy and loneliness cannot be fully explained by an overlap with depressive symptoms and highlights a unique role with respect to loneliness. Our finding that depressive symptoms accounted for the association between loneliness and disorganised schizotypy is in line with a previous study (Jaya et al., 2017), and may reflect the cognitive effects of depression (Rock et al., 2014).

Our results showed that higher positive schizotypy is related to higher loneliness when examined individually, as previously shown (Lamster et al., 2017b; Riggio and Kwong, 2009; Sündermann et al., 2014). Surprisingly, we found that positive schizotypy was associated with lower loneliness when negative and disorganised dimensions and depression were accounted for. This may be due to a suppressor effect (Paulhus et al., 2004). The shared variance caused by overlap between dimensions is removed, revealing a unique association between positive schizotypy and lower loneliness. A similar pattern was observed in a recent experience-sampling study measuring social functioning and affect across schizotypal dimensions (Kwapil et al., 2020). The potential protective effects of positive schizotypy against loneliness may be explained by aspects, such as magical thinking, which has been linked to creativity, well-being, openness to experience and spiritual connectedness (Badzakova-Trajkov et al., 2011; Crespi et al., 2019; Mohr and Claridge, 2015; Polner et al., 2018). In healthy individuals, magical

thinking may function as a cognitive defence mechanism, by which individuals attempt to rationalise about the uncertainties of life (Williams and Irwin, 1991). This mechanism may be governed by an adaptive cognitive style, by which individuals allow rational thinking and magical thinking to complement each other. By contrast, individuals high in disorganised schizotypy and those with schizophrenia may lack the cognitive reasoning ability needed to meaningfully integrate magical experiences in an adaptive framework, and instead tend to attribute such experiences to randomness (Williams and Irwin, 1991). In support of this theory, the association between schizotypy and affective response to paranormal experiences has been found to be moderated by cognitive disorganisation (Schofield and Claridge, 2007). It has been reported that individuals with high cognitive disorganisation describe their paranormal experiences as distressing, whereas those with low cognitive disorganisation describe them as pleasant (Schofield and Claridge, 2007). Others reported associations between magical thinking and odd beliefs and the tendency to believe in conspiracy theories was mediated by the degree of analytical thinking (Barron et al., 2018). This highlights a potentially protective role of paranormal beliefs and magical thinking, as moderated by cognitive organisation. If the link between positive schizotypy and increased loneliness is indeed mediated by disorganised schizotypy, a larger focus on cognitive remediation strategies may be useful to target loneliness within this population.

4.2. COVID-19 and mental health

Our findings that loneliness and depressive symptoms were higher during the COVID-19 pandemic than before are in line findings of others (Esteves et al., 2021; Jia et al., 2020; Killgore et al., 2020; Li et al., 2020; Palgi et al., 2020). This underlines the negative impact of the pandemic on mental health in students, which likely depends on many factors. Participants who were assessed during the pandemic may have differed in terms of perceived risk of developing a mental health problem and loneliness, as well as in their willingness to talk about it, due to an increased focus on these topics in the media. Such media coverage may have primed participants to answer a certain way, however it may also have increased the awareness about mental health in general, which may have reduced stigmatisation and in turn increased individuals' willingness to admit to experiencing challenges. It may be useful for future studies to explore perceptions of mental health stigmatisation and prevalence, to gain further insights into these mechanisms.

4.3. Conclusion

Loneliness was associated with all three schizotypy dimensions individually, but when examined in conjunction it was most strongly associated with negative schizotypy and depression. This highlights the importance of investigations into the three-dimensional model of schizotypy to gain a better understanding of loneliness across the psychosis continuum and suggests that social motivation and anhedonia could be key targets for loneliness interventions. Further research is necessary to examine the directionality of effects.
